II. INTRODUCTION

This guideline is intended as an educational resource for health care providers who treat injured workers in the Washington workers’ compensation system under Title 51 RCW and as review criteria for the department’s utilization review team to help ensure treatment of shoulder injuries is of the highest quality. The emphasis is on accurate diagnosis and treatment that is curative or rehabilitative (see WAC 296-20-01002 for definitions).

This guideline, focusing on work-related shoulder conditions, was developed in 2013 by a subcommittee of the statutory Industrial Insurance Medical Advisory Committee (IIMAC). One of the committee’s goals is to provide standards that ensure a uniformly high quality of care for injured workers in Washington State.

The subcommittee is comprised of a group of physicians of various medical specialties, including rehabilitation medicine, occupational medicine, orthopedic surgery and family practice. The subcommittee based its recommendations on the weight of the best available clinical and scientific evidence from a systematic review of the literature, and on a consensus of expert opinion when scientific evidence was insufficient.

Shoulder pathologies are common in both the workers’ compensation and general populations. Accurate assessment and treatment are critical to ascertaining work-relatedness and facilitating the worker’s return to health and productivity.

III. ESTABLISHING WORK-RELATEDNESS

Shoulder conditions are a common cause of pain and disability among adults, with a prevalence of 7-10% \(^5\). A shoulder condition may arise from acute trauma or, in some circumstances, from non-traumatic industrial activities.

Risk factors associated with shoulder conditions include trauma, overuse, inflammation, age-related tissue degeneration, and smoking \(^6\). A careful history is needed both for elucidating the mechanism of injury and for establishing causation.

A. Shoulder conditions as industrial injuries:

A shoulder condition may be induced acutely, e.g. a patient falls on an outstretched hand and experiences concomitant trauma. To establish a diagnosis of a shoulder condition as a work-related injury, the provider must give a clear description of the traumatic event leading to the injury (See Table 1).

B. Shoulder conditions as occupational diseases:

Work-related activities may cause or contribute to the development of shoulder conditions caused by chronic exposures. Conditions that support work-relatedness are:
1. Carrying/lifting heavy loads on or above the shoulders, or carrying with hands.
2. Pushing/pulling heavy loads.
3. Working with arms above the shoulder for more than 15 minutes at intervals.
4. Repetitive arm/wrist movements combined with force for long periods.

To establish a diagnosis of an occupational disease, all of the following are required:

1. Exposure: Workplace activities that contribute to or cause shoulder conditions, and
2. Outcome: A diagnosis of a shoulder condition that meets the diagnostic criteria in this guideline, and
3. Relationship: Generally accepted scientific evidence, which establishes on a more probable than not basis (greater than 50%) that the workplace activities (exposure) in an individual case contributed to the development or worsening of the condition relative to the risks in everyday life. In epidemiological studies, this will usually translate to an odds ratio (OR) ≥ 2.

In order for a shoulder condition to be allowed as an occupational disease, the provider must document that the work exposures created a risk of contracting or worsening the condition relative to the risks in everyday life, on a more-probable-than-not basis. (Dennis v. Dept. of Labor and Industries, 1987).

When the Department receives notification of an occupational disease, the Occupational Disease & Employment History form is mailed to the worker, employer or attending provider. The form should be completed and returned to the Department as soon as possible. If the worker’s attending provider completes the form, provides a detailed history in the chart note, and gives an opinion on causality, he or she may be paid for this (use billing code 1055M). Additional billing information is available in the Attending Doctor’s Handbook.
### Table 1: Exposure and Risk

<tr>
<td>Moderate lifting</td>
<td>Grocery checkers</td>
<td>Low</td>
<td>Injury or occupational disease</td>
</tr>
</tbody>
</table>

There is no substantial scientific evidence to support the existence of “overuse syndrome”, i.e. an injury to one extremity causing the contralateral extremity to be damaged by overuse.

### IV. MAKING THE DIAGNOSIS

A case definition for a shoulder condition includes appropriate symptoms, objective physical findings and abnormal imaging. A presumptive diagnosis may be based on symptoms and objective findings, but the diagnosis usually requires confirmation by clinical imaging prior to proceeding to surgery.

#### A. History and clinical exam

A thorough occupational history is essential for determining whether a shoulder condition is work-related, and whether it is due to an acute or chronic exposure. The provider should take extra care in documenting the reasons for diagnosing an occupational disease, as multiple employers might share liability. Providers should document the exposure and submit a complete work history as soon as a diagnosis of occupational disease is made; see “Establishing Work-Relatedness”.

Although nonspecific and non-diagnostic, the primary symptom associated with most shoulder conditions is pain at night and pain with movement. The primary symptom associated with most rotator cuff tears is weakness: with elevation, internal/external rotation, and/or abduction testing. Some shoulder conditions, like dislocations, show marked deformity.

Physical examination should consist of accepted test and examination techniques applicable to the joint area being examined. Clinical judgment should be applied when considering which test
to perform, for example Neer’s, Abduction, and O’Brien’s tests. For details of commonly used shoulder tests see Appendix 1.

B. Diagnostic imaging
Conventional X-ray, MRI, and ultrasound are the best imaging tools to corroborate the diagnosis of a shoulder condition [7-11]. MRI has been considered the gold standard; however, research has demonstrated the efficacy of ultrasound, done by a skilled provider or technician, to diagnose rotator cuff tears. A systematic review found ultrasound to have a pooled sensitivity of .95 and specificity of .96 in detecting full thickness rotator cuff tears [7]. Ultrasound was nearly as effective as MRI in diagnosing partial tears, therefore ultrasound may be recommended to diagnose full and partial thickness tears [9].

Contrast MRI is not necessary to diagnose rotator cuff tears, but may be considered when there is suspicion of a SLAP lesion/tear. [12, 13].

V. TREATMENT

A. Conservative treatment
Shoulder injuries may be complex, often involving more than a single tissue or anatomic element. Different shoulder problems can present with similar findings, such as limited, painful motion and tenderness. It is important to consider which components of the shoulder girdle may be affected and tailor a conservative treatment plan accordingly. Published reports have reported utility for a variety of conservative interventions to reduce pain and improve function for a number of shoulder conditions. However, well designed research studies on conservative care for musculoskeletal injuries are limited in both quantity and quality.

The following is an example of a conservative intervention treatment algorithm:

- Non-steroidal anti-inflammatory (NSAID) medications and acetaminophen may be considered to treat pain [14].
- Brief rest and immobilization (less than 4 days) in the early stage, however, early unloaded movement and manual interventions such as mobilization and manipulation have been reported to reduce symptoms and facilitate greater shoulder motion, especially with acromioclavicular injuries [15].
- Immobilization beyond 3 days carries the risk of a frozen shoulder and is therefore not recommended, with the exception of fractures or glenohumeral dislocations.
- Therapeutic exercise and mobilization to improve shoulder range of motion and strength, and decrease pain in soft tissue injuries such as shoulder sprain, rotator cuff tendonitis or tears, and glenohumeral dislocations [16-18].
- Incorporating strengthening exercise once range of motion is increased and pain is reduced [18].
Corticosteroid injections, typically within the subacromial space have been reported to provide short term relief for adhesive capsulitis, rotator cuff tendinopathy, impingement syndrome, tendon disorders, and SLAP disorders [19-22]. Care must be exercised when giving a corticosteroid injection to a partial rotator cuff tear, as this may lead to tear extension. Because corticosteroid use is associated with side effects such as weakening of connective tissue, no more than 3 injections are recommended under one claim for the shoulder, 4 injections per lifetime.

Ergonomic interventions such as work station and/or work flow modification appear to be helpful in sustaining return to work [23-25].

Any worker who does not gain meaningful functional improvement (30-50%) within 4-6 weeks of conservative treatment should be considered for a specialist consultation. Meaningful functional improvement may best be determined using validated shoulder/arm function instruments such as the Simple Shoulder Test (SST)[26], the Shoulder Pain and disability Index (SPADI)[27, 28], the DASH or Quick DASH[29-32] or the American Shoulder and Elbow Surgeons Assessment (ASES)[30] form.

B. Surgical treatment
Shoulder surgeries under workers’ compensation must be pre-authorized by utilization review. Criteria for authorizing shoulder surgery are contained in the review at the beginning of this guideline. If a proposed surgery is not listed, other standard review criteria may be used. For further information on utilization review, see
http://www.lni.wa.gov/ClaimsIns/Providers/AuthRef/UtilReview/default.asp

VI. SPECIFIC CONDITIONS

A. Rotator cuff tears
Rotator cuff tears can be acute or chronic in onset, and will vary in the thickness of the tissue tear and the presentation of signs and symptoms.

As industrial injury:
A worker presenting with acute pain suspicious for a rotator cuff tear should be able to report a precipitating traumatic event, such as a severe fall on an outstretched arm or an episode of heavy overhead lifting.

As occupational disease:
Chronic exposure risk factors for rotator cuff tears include heavy repetitive overhead work, such as in the examples in Table 1. However, many rotator cuff tears are due to non-work related conditions, such as age-related degeneration. The likelihood of having a rotator cuff tear increases with age. Studies show that more than half of individuals 60 and over have partial or
complete tears, yet are asymptomatic and have no history of trauma\textsuperscript{[33]}. Smoking has also been associated with rotator cuff tears\textsuperscript{[1]}.

**Diagnosis and treatment**

A careful occupational history and good clinical exam are most important in making a diagnosis of a rotator cuff tear and relating it to work exposures. Nonspecific symptoms reported with rotator cuff tears are pain with movement and pain at night. Objective clinical findings include weakness on testing forward elevation; internal rotation and abduction (subscapularis); and external rotation (infraspinatus).

Ultrasound and conventional MRI are the best imaging tools for diagnosing rotator cuff tears\textsuperscript{[9, 11]}. MRI remains the gold standard in the radiographic assessment of rotator cuff tears\textsuperscript{[34]}. X-ray or CT arthrogram is appropriate if there is a contraindication to an MRI. Contrast MRI is not necessary for making the diagnosis of a rotator cuff tear. Arthroscopy for the purpose of diagnosing rotator cuff tears is not appropriate.

Symptomatic, full-thickness rotator cuff tears, especially in a young worker, should be surgically repaired as soon as possible because of increased risk of tear progression\textsuperscript{[35]}. For a rotator cuff tear that was previously treated conservatively, worsening pain usually indicates tear progression or migration of the humeral head\textsuperscript{[36-38]} and could warrant operative care. Tears that are found incidentally and are asymptomatic are generally not work related and tend to get better with conservative care.

Partial tears, small tears and chronic full thickness tears in individuals >65 years old should be treated conservatively before surgery is considered\textsuperscript{[6]}. Many workers, regardless of age, will recover function without surgery; there is limited risk of developing irreversible chronic changes such as a fatty infiltration, tendon retraction or cuff tear arthropathy when conservative care is initiated.

Injured workers with full or partial thickness tears may continue to work with restricted use of involved extremity, if work accommodation is allowed.

Rotator cuff repairs are increasingly done arthroscopically. Evidence does not support a difference in outcomes accorded to surgical technique, whether it is arthroscopic, mini-open or single or double row techniques\textsuperscript{[39]}. Acromioplasty is not usually necessary during a rotator cuff repair; acromioplasty does not change functional outcome after arthroscopic repair of the rotator cuff.\textsuperscript{[40-43]}.
** Tissue Grafts (i.e., acellular human dermal matrix)

The use of xenografts and allografts is currently not covered, given clinical concerns about localized reactions and a lack of studies demonstrating superiority to conventional techniques. There is an increased risk of infection and rejection reported with the use of xenografts and there is no difference in outcome when they are used \(^\text{[44]}\).

** Distal clavicle resection as a routine part of acute rotator cuff tear repair is not covered.

Revision rotator cuff repairs

Nicotine has been associated with delayed tendon-to-bone healing after rotator cuff tear repair surgery \(^\text{[1-3]}\). It is strongly recommended that revision surgery not be performed in current nicotine users. Revision rotator cuff surgery should not be done if a patient has a massive rotator cuff tear (i.e. tears > 3cm or with severe fatty infiltration). The outcome of revision surgery for symptomatic failed primary repairs is inferior to a successful primary repair \(^\text{[45]}\).

A second revision surgery or subsequent surgeries will only be considered if compelling evidence exists that the injured worker had returned to a state of clinically meaningful functional improvement (at least 30%) after the last revision surgery, followed by an ongoing significant decline in function. Measures of functional improvement should be documented on a validated instrument (e.g. DASH, SST, SPADI, and ASES) for a second revision surgery to be allowed.

B. Subacromial impingement syndrome without a rotator cuff tear

Subacromial impingement syndrome (SIS) results when the soft tissues of the glenohumeral joint, between the coracoacromial arch and the humeral tuberosity, are compressed, disturbing the normal sliding mechanism of the shoulder when the arm is elevated. SIS can be an occupational disease. Occurrence has been associated with heavy overhead work, high force and repetition \(^\text{[46]}\).

Diagnosis and treatment

Workers may report generalized shoulder pain. An objective clinical finding is pain with active elevation. To confirm the diagnosis of SIS, an MRI should reveal evidence of tendinopathy/tendinitis or a rotator cuff tear.

Non-operative treatments of SIS have been shown to be as effective as subacromial decompression \(^\text{[47, 48]}\). For decompression to be allowed for SIS, the diagnosis must be verified by pain relief from a subacromial injection of local anesthetic, and the worker must have failed to improve function and decrease pain after twelve weeks of conservative care.

Subacromial decompression is also a reasonable treatment option for massive, irreparable rotator cuff tears that are not amenable to repair.
C. Calcific tendonitis
The exact etiology of calcific tendonitis is still unknown. It does, however, affect up to 10-20% of the population between the ages of 30-50 [49-51].

Diagnosis and Treatment

The diagnosis of calcific tendonitis is typically made with conventional plain films alone. Calcific tendonitis is not always symptomatic. When calcific tendonitis is symptomatic, non-operative treatment of the condition is typically successful [49, 52]. If symptoms continue after 12 weeks of conservative management then debridement of the calcified tendon is reasonable.

D. Acromioclavicular dislocation
Acute acromioclavicular (AC) injury is typically referred to as shoulder dislocation. The degree of clavicular displacement depends on the severity of the injury. The injury is classified using the Rockwood Classification [53].

Diagnosis and treatment

AC dislocations (Types III-VI) show marked deformity, and are accompanied by pain and tenderness over the AC joint. Conventional X-ray is the best imaging tool to use when AC dislocation is suspected.

Table 2: Rockwood Classification of acromioclavicular injuries

<table>
<thead>
<tr>
<th>Rockwood classification</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Type I:</strong> Sprain of the acromioclavicular or coracoclavicular ligament.</td>
</tr>
<tr>
<td><strong>Type II:</strong> Subluxation of the acromioclavicular joint associated with a tear of the acromioclavicular ligament; coracoclavicular ligament is intact.</td>
</tr>
<tr>
<td><strong>Type III:</strong> Dislocation of the acromioclavicular joint with injury to both acromioclavicular and coracoclavicular ligaments.</td>
</tr>
<tr>
<td><strong>Type IV:</strong> Clavicle is displaced posteriorly through the trapezius muscle.</td>
</tr>
<tr>
<td><strong>Type V:</strong> Gross disparity between the acromion and clavicle, which displaces superiorly.</td>
</tr>
<tr>
<td><strong>Type VI:</strong> Dislocated lateral end of the clavicle lies inferior to the coracoid.</td>
</tr>
</tbody>
</table>

*Types I-III are common, while types IV-VI are rare.

Surgery is not covered for type I and II injuries, whereas surgery is usually indicated for types IV, V, and VI. Management of type III injuries is more controversial but most patients with type III AC joint dislocations are best treated conservatively. Surgery should be considered only when at least 3 months of conservative care fails. For patients with a type III dislocation and high
physical demands on the shoulder, early orthopedic surgical consultation and/or surgery may be indicated.

**E. Labral tears, including superior labral anterior-posterior (slap) tears**
Labral lesions constitute a wide range of pathology. The most common labral lesions are SLAP tears which are superior labral tears that extend anteriorly and posteriorly. Some SLAP tears result from acute trauma and others are degenerative in nature. There are several types of SLAP tears; type II SLAP tears are the most common and constitute more than fifty percent of all tears [54, 55].

**Table 3: Types of SLAP tears**

<table>
<thead>
<tr>
<th>Tear type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Fraying of the labrum without detachment from glenoid.</td>
</tr>
</tbody>
</table>
| II        | The labrum is completely torn off the glenoid. Type II SLAP tears are subdivided into  
|           | a) Anterior  
|           | b) Posterior  
|           | c) Combined anterior and posterior. |
| III       | “Bucket handle tear”: the torn labrum hangs into the joint and causes symptoms of “locking, popping”. |
| IV        | Labral tear extends into the long head of the biceps tendon. |

**Diagnosis and treatment**

No single examination technique is highly specific or sensitive in diagnosing labral tears because patients often have concomitant pathology. Some signs and symptoms include locking, popping, and grinding sensation, and pain worse when doing activities [56]. Physical exam (e.g. O’Brien’s test, Neer’s test, Yergason’s test) may be used to strengthen a diagnosis, but the decision to proceed to operative management should be based on imaging findings. Conventional MRI may be used, but MRI with contrast has the highest reported sensitivity and specificity for the diagnosis of SLAP tears [12, 57-60].

Since most SLAP tears are associated with other pathology, the provider should identify other shoulder conditions, if any, and follow appropriate surgical indications. Operative treatment for labral tears depends on the type of tear that is present. Type I tears are mostly debrided, type II tears are repaired using one of the several arthroscopic techniques [61] and types III and IV tears involving the biceps are repaired by tenotomy or tenodesis [61-65]. Literature suggests that there are no advantages to repairing type II lesions associated with rotator cuff tears in patients over the age of 50 [63]. Indications for surgery for SLAP tears are not standardized and remain somewhat controversial. Expert opinion, including the American Academy of Orthopedic Surgeons, recommends initial conservative care management for SLAP tears. In general
conservative care management should last a minimum of 6-12 weeks. Early surgery should be considered only in cases where there is evidence of symptomatic suprascapular nerve compression.

**F. Acromioclavicular arthritis**
Acromioclavicular (AC) arthritis may result from previous trauma to the joint or may be the result of heavy lifting over a period of time.

**Diagnosis and treatment**
Symptoms include pain and tenderness at the AC joint. Symptomatic AC arthritis may initially improve with steroid injection. During rotator cuff repair, the decision to resect the distal clavicle should be based upon x-ray, MRI (radiologist-interpreted) or bone scan showing moderate to severe AC joint arthritis, distal clavicle edema or distal clavicle osteolysis.

**Claviculectomy/Mumford as an add-on or as a stand-alone procedure should meet all criteria (criteria table) and should not be done without the specified objective findings. It is important to document the source of pain, including pain relief with local anesthetic injection.**

**Prior authorization is required. The routine use of the Mumford procedure during a rotator cuff tear repair will not be approved.**

**G. Glenohumeral dislocation**
Glenohumeral dislocations typically involve a soft tissue injury, such as a rotator cuff tear or a tear of the glenohumeral ligament.

**Diagnosis and treatment**
Swelling, weakness and numbness are the main symptoms. Dislocations that are not accompanied by tears can be treated by reduction of the humeral head and initial immobilization followed by structure rehabilitation.

Surgical interventions have been shown to reduce the rate of recurrent instability in young (under 35) active patients with first-time dislocation. When a dislocation is associated with a rotator cuff tear, then repair of the tear is appropriate without additional conservative care. If the dislocation is associated with a labral tear, then initial conservative care is reasonable.

If instability persists after 6 weeks of conservative care, surgery is warranted. Surgery may also be appropriate if there is a history of more than one dislocation in a 3 month period. Arthroscopic and open labral/Bankart (capsulorraphy) repairs yield similar results in regard to recurrent instability, clinical outcomes and post-operative osteoarthritis. **Thermal capsulorrhaphy is not covered**, as there is no evidence of benefit.
It is not the intent of the department to accept treatment for multi-directional instability that pre-dates injury.

H. Tendon rupture or tendinopathy of the long head of the biceps
Tendinopathy of the long head of the biceps most commonly presents in combination with rotator cuff tears, SLAP lesions, and bursitis.

Diagnosis and treatment

Patients typically present with increasing anterior shoulder pain, declining function and a history of chronic repetitive overhead use. An MRI or an ultrasound may reveal tendinopathy, a partial tear or a complete tear of the tendon; however all imaging studies lack sensitivity and specificity as compared to arthroscopy.

For proximal long head biceps tendon rupture, active participation in conservative treatment is often successful; however in a young active patient surgery may be indicated. Nonsurgical management should be initiated for tendinopathy. Surgery may be considered for symptomatic partial tears and medial subluxation of the tendon. Tenotomy and tenodesis have comparable favorable results in literature, with the only major difference being a higher incidence of deformity with biceps tenotomy \[62,71\]. Tenodesis is typically preferred for younger patients to avoid a cosmetic deformity \[72\].

I. Glenohumeral arthritis and arthropathy
Treatment of degenerative conditions such as glenohumeral arthritis or rotator cuff tear arthropathy is generally initiated with non-operative management techniques such as NSAID’s and physical therapy. Conservative management is not, however, mandatory if severe degenerative changes are noted on conventional x-rays as the likelihood of meaningful long term relief is negligible.

Arthroplasties are a treatment option for acute comminuted fractures, post-traumatic arthritis, glenohumeral arthritis, and rotator cuff tear arthropathy. Total shoulder arthroplasties are primarily used to treat glenohumeral arthritis. Reverse shoulder arthroplasties have become the treatment of choice for the management of rotator cuff tear arthropathy where the glenohumeral arthritis is associated with a chronic rotator cuff tear and a high riding humerus.

All conditions are heralded by pain and limitations in range-of-motion. Conventional x-rays are typically sufficient to make the diagnosis of any of the preceding conditions.

Highly comminuted fractures of the proximal humerus may not always be reparable. If deemed irreparable then proceeding to a hemi-arthroplasty urgently or emergently is reasonable.
J. Manipulation under anesthesia/arthroscopic capsular release
Manipulation under anesthesia, or arthroscopic capsular release, may be considered if a patient has persistent stiffness, typically after a procedure that has not responded to at least 12 weeks of physical therapy and/or directed home exercises.

K. Diagnostic arthroscopy
Diagnostic arthroscopy is not currently accepted as a viable treatment option. If conventional x-rays and a MRI are unable to identify an anatomic explanation for a workers pain then surgery should not be performed.

VII. POST OPERATIVE TREATMENT AND RETURN TO WORK
It is important for the attending provider and the surgeon to focus on preoperative planning for postop recovery, reactivation and return to work activities. During the immediate postop period, (6 weeks) the surgeon should be involved in helping to direct these activities.

Unless a patient has multiple injuries, return to work within 6 weeks after surgery is reasonable if appropriate modifications are available.

Work accommodation during the early recovery periods with conservative interventions appear to be well supported. Jobsite modifications are dependent on the nature of the patient’s work tasks, their injury, and their response to rehabilitation. Typically, factors such as lifting, pulling, and repetitive overhead work require modifications in position, force, repetitions, and/or duration. Those workers returning to jobs with heavy lifting or prolonged overhead work may need additional weeks of rehabilitation to regain full strength.
# VII. SPECIFIC SHOULDER TEST

## Specific shoulder tests

### Rotator cuff impingement

- **Neer’s test** assesses for possible rotator cuff impingement. Stabilize the scapula (place your hand firmly upon the acromion, or hold the inferior angle of the scapula with your hand) and with the thumb pointing down and passively flex the arm. Pain is a positive test.

- **Hawkins test** assesses for possible rotator cuff impingement. Stabilize the scapula, passively abduct the shoulder to 90 degrees, flex the shoulder to 30 degrees, flex the elbow to 90 degrees, and internally rotate the shoulder. Pain is a positive test.

### Rotator cuff tears

- **Abduction test** – Active abduction to 90 degrees while providing resistance proximal to the elbow (primary abductor: supraspinatus).

- **External rotation** test – Examiner places one hand on the medial elbow and the other on the lateral aspect of the distal forearm. Instruct the patient to externally rotate the shoulder while you provide resistance. It is important to stabilize the patient's elbow against their side to prevent them from substituting abduction for external rotation. Compare the strength of the involved shoulder with that of the uninvolved shoulder. This test may also elicit pain indicating inflammation and weakness in the external rotators (primary external rotator: infraspinatus).

- **Lateral Jobe test** – Patient holds their arm at 90 degrees abduction in the coronal plane with elbows flexed at 90 degrees and hands pointing inferiorly with the thumbs directed medially. A positive test consists of pain or weakness on resisting downward pressure on the arms or an inability to perform the tests.

### Acromioclavicular joint test

- **Crossed arm adduction**: Flex the shoulder to 90 degrees and adduct arm across body (reaching for opposite shoulder). Pain at the acromioclavicular joint is a positive test.

### Labral tears, tendon disorders, dislocations

- **O'Brien’s test**: point the thumb down,

- Flex shoulder to 90 degrees and adduct the arm across midline. Provide resistance against further shoulder flexion and evaluate for pain. Repeat with thumb pointing up and again evaluate for pain. If pain was present with the thumb down but relieved with the thumb up, it is considered a positive test, suspicious for a labral tear.
• **Yergason’s** test: flex elbow to 90 degrees, shake hands with patient and provide resistance against supination. Pain indicates possible bicipital tendinopathy or a labral tear.

• **Speed’s** test: flex the shoulder to 90 degrees with the arm supinated. Provide downward resistance against shoulder flexion. Pain indicates possible bicipital tendinopathy or a labral tear.

• **Biceps load** test: supinate the arm, abduct shoulder to 90 degrees, flex elbow to 90 degrees, externally rotate arm until patient becomes apprehensive and provide resistance against elbow flexion. Pain indicates possible bicipital tendinopathy or a labral tear.

• **Apprehension** test: evaluates for anterior glenohumeral stability. With the patient supine, abduct shoulder to 90 degrees and externally rotate arm to place stress on the glenohumeral joint. If the patient feels apprehension that the arm may dislocate anteriorly, the test is positive. The apprehension test is usually followed by the relocation test: with hand, place a posteriorly directed force on the glenohumeral joint. Relief of apprehension for dislocation is a positive test.

IX. FUNCTIONAL DISABILITY SCALES FOR SHOULDER CONDITIONS

The Simple Shoulder Test (SST) and the Shoulder Pain and Disability Index (SPADI) are publically available and free of charge. They are reproduced on the following pages.

The DASH and *QuickDASH* can be obtained by individual clinicians from the Institute for Work and Health, [http://www.dash.iwh.on.ca/](http://www.dash.iwh.on.ca/)

The American Shoulder and Elbow Surgeons (ASES) also have a measurement tool that is proprietary.
Simple Shoulder Test (SST)

**Simply circle Yes or No**

1. Is your shoulder comfortable with your arm at rest by your side?  
   Yes  No
2. Does your shoulder allow you to sleep comfortably?  
   Yes  No
3. Can you reach the small of your back to tuck in your shirt with your hand?  
   Yes  No
4. Can you place your hand behind your head with the elbow straight out to the side?  
   Yes  No
5. Can you place a coin on a shelf at the level of your shoulder without bending your elbow?  
   Yes  No
6. Can you lift 1 lb (a full pint container) to the level of your shoulder without bending your elbow?  
   Yes  No
7. Can you lift 8 lb (a full gallon container) to the level of the top of your head without bending your elbow?  
   Yes  No
8. Can you carry 20 lb (a bag of potatoes) at your side with the affected arm?  
   Yes  No
9. Do you think you can toss a softball underhand 10 yards with the affected arm?  
   Yes  No
10. Do you think you can throw a softball overhand 20 yards with the affected arm?  
    Yes  No
11. Can you wash the back of your opposite shoulder with the affected arm?  
    Yes  No
12. Would your shoulder allow you to work full-time at your regular job?  
    Yes  No

Score (Total # of No’s)__________

Shoulder Pain and Disability Index (SPADI)

How severe is your pain?

1. At its worst: \[(\text{No pain}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{Worst Pain Imaginable})\]
2. When lying on involved side: \[(\text{No pain}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{Worst Pain Imaginable})\]
3. Reaching for something on a high shelf: \[(\text{No pain}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{Worst Pain Imaginable})\]
4. Touching the back of your neck: \[(\text{No pain}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{Worst Pain Imaginable})\]
5. Pushing with the involved arm: \[(\text{No pain}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{Worst Pain Imaginable})\]

How much difficulty do you have?

1. Washing your hair: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
2. Washing your back: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
3. Putting on an undershirt or pullover sweater: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
4. Putting on a shirt that buttons down the front: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
5. Putting on your pants: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
6. Placing an object on a high shelf: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
7. Carrying a heavy object of 10 pounds: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
8. Removing something from your back pocket: \[(\text{No difficulty}) \ 0 \ 1 \ 2 \ 3 \ 4 \ 5 \ 6 \ 7 \ 8 \ 9 \ 10 \ (\text{So difficult - help is required})\]
